A mineral can have many different crystalline forms. The champion in this regard is calcite or calcium carbonate (CaCO₃), the main constituent of limestone.

Calcite, in all its multiplicity

Calcite is one of the commonest minerals on earth — but fascinating for all that! It holds the record for having the highest number of distinct forms. Haüy described nearly 100 of these. Palache recorded 630 and Goldschmidt 2544. These forms are sometimes classed in four main categories: rhombohedra, prisms, scalaphedra and bipyramids.

Faces, growth rates, clusters...

The different faces of a crystal have different rates of growth. These rates depend on the structure of the crystal, and also the conditions of growth, such as temperature, pressure and impurities in the composition of the mother liquid. The forms generated may or may not be randomly associated, all of which results in an extraordinary diversity.

Atlas des Krystallformen

A plate from Goldschmidt's Atlas, in which he presents drawings of 2544 different forms of calcite. Example of the four principle volumes: rhombohedron prism, scalaphedron and bipyramid.
